

Support Vector Machine Multiuser Receiver for DS-CDMA Signals in Multipath Channels

S. Chen, A. K. Samingan, and L. Hanzo

Abstract—The problem of constructing an adaptive multiuser detector (MUD) is considered for direct sequence code division multiple access (DS-CDMA) signals transmitted through multipath channels. The emerging learning technique, called support vector machines (SVMs), is proposed as a method of obtaining a nonlinear MUD from a relatively small training data block. Computer simulation is used to study this SVM MUD, and the results show that it can closely match the performance of the optimal Bayesian one-shot detector. Comparisons with an adaptive radial basis function (RBF) MUD trained by an unsupervised clustering algorithm are discussed.

Index Terms—Direct sequence code division multiple access (DS-CDMA), linear MMSE detector, multiuser detector (MUD), multiuser interference, optimal one-shot detector, support vector machines, unsupervised clustering.

I. INTRODUCTION

DIRECT-sequence code-division multiple-access (DS-CDMA) [1] constitutes an attractive multiuser scheme that allows users to transmit at the same carrier frequency in an uncoordinated manner. However, this creates multiuser interference (MUI) which, if not controlled, can seriously degrade the quality of reception. Mutually orthogonal spreading codes for different users can provide an inherent immunity to MUI in the case of synchronous systems. Unfortunately, multipath distortions are often encountered in DS-CDMA systems and will reduce this inherent immunity to MUI. A variety of receivers, known as multiuser detector (MUDs), have been proposed for DS-CDMA systems [2]–[4]. In a DS-CDMA system, the objective of the receiver is to detect the transmitted information bits of one (at mobile-end) or many (at base station) users. In this paper, the first case is considered. This is usually referred to as the downlink scenario, the communication channel from base station to mobile. In particular, the one-shot detector, that is, the receiver detecting a user bit at a bit period, is studied. Furthermore, we will concentrate on the scenario where a few strong interfering users exist, as the use of an MUD is especially effective in such a situation.

For such applications, the linear minimum mean square error (MMSE) MUD [5]–[9] is widely used, as it is computationally very simple and can readily be implemented using standard adaptive filter techniques. A more complicated linear minimum bit error rate MUD has also been studied [10]–[14]. Linear detectors, however, can only work when the underlying noise-free signal classes are linearly separable. As nonlinear separable

cases are common in DS-CDMA channels, neural networks have been considered as nonlinear MUDs. In the work [15], a multilayer perceptron (MLP) was applied to a CDMA system without intersymbol interference (ISI). The experience shows that the MLP MUD has better performance than the linear MUD but training times are long and unpredictable. Mitra and Poor [16] applied a RBF network to the same problem. An advantage of the RBF MUD is its intimate link with the optimal one-shot detector. Training times are better and more predictable than the MLP. A RBF receiver [17] was also considered for channels with memory, and a Volterra series detector was explored [18].

A learning technique known as the SVM has recently gaining popularity due to its many attractive features and promising empirical performance [19]–[26]. The formulation of SVM embodies the structural risk minimization (SRM) principle, as opposed to the empirical risk minimization (ERM) approach commonly employed in statistical learning. SRM minimizes an upper bound on the generalization error, as opposed to ERM which minimizes the error on the training data. It is this difference which equips SVMs with a greater potential to generalize. For binary classification tasks, the SVM approach nonlinearly maps the input space into a high-dimensional feature space via simple kernel representations. In the high-dimensional feature space, a linear classifier with maximum margin is constructed. Apart from good generalization properties, the learning aspect of SVMs is intriguing. An SVM classifier is determined only by a sparse set of support vectors (SVs), and these SVs are automatically selected from the training data during the learning process.

The SVM technique has been applied to channel equalization [27]–[30]. These studies have shown that the SVM approach is very effective in overcoming ISI and cochannel interference. As the idea of SVM is originated from finding an optimum hyperplane to separate two classes with maximum margin, it is also very relevant to multiuser detection in DS-CDMA. In this paper, the SVM technique is investigated as an adaptive nonlinear MUD. Our study shows that an SVM MUD trained using a relatively small block of noisy received signal samples can closely approximate the optimal MUD which requires a complete knowledge of the system. The remainder of the paper is organized as follows. Section II presents the DS-CDMA system model used and provides the necessary notations and definitions. Section III summarizes the linear MMSE MUD and the optimal Bayesian one-shot MUD. In Section IV, the proposed SVM MUD is presented. Section V gives some computer simulation results, comparing the performance of the SVM MUD with those of the linear and optimal MUDs. Section VI compares the adaptive SVM MUD with a RBF MUD trained by

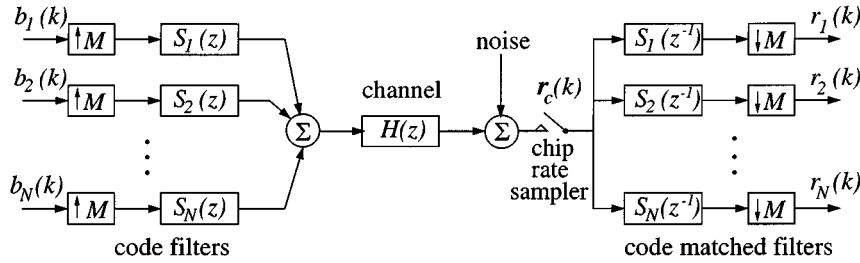

Fig. 1. Discrete-time model of synchronous CDMA downlink.

an unsupervised clustering algorithm [31]–[34]. The paper concludes in Section VII.

II. SYSTEM MODEL

Using notations from the multirate filtering literature [35], the discrete-time model of the synchronous DS-CDMA system with N users and M chips per bit is depicted in Fig. 1, where $b_i(k) \in \{\pm 1\}$ denotes the k th bit of user i , the signature code sequence for user i

$$\bar{s}_i = [\bar{s}_{i,1} \cdots \bar{s}_{i,M}]^T \quad (1)$$

is normalized to have a unit length, and the transfer function of the channel impulse response (CIR) is

$$H(z) = \sum_{i=0}^{n_h-1} h_i z^{-i}. \quad (2)$$

It is assumed that $N < M$. The bit vector of N users at k is

$$\mathbf{b}(k) = [b_1(k) \cdots b_N(k)]^T \quad (3)$$

and the received signal vector after the chip-matched filters is

$$\mathbf{r}(k) = [r_1(k) \cdots r_N(k)]^T. \quad (4)$$

The baseband model for $\mathbf{r}(k)$ can be represented by [36]

$$\begin{aligned} \mathbf{r}(k) &= \bar{\mathbf{S}}^T \mathbf{H} \begin{bmatrix} \bar{\mathbf{S}}\mathbf{A} & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \bar{\mathbf{S}}\mathbf{A} & \ddots & \vdots \\ \vdots & \ddots & \ddots & \mathbf{0} \\ \mathbf{0} & \cdots & \mathbf{0} & \bar{\mathbf{S}}\mathbf{A} \end{bmatrix} \\ &\quad \cdot \begin{bmatrix} \mathbf{b}(k) \\ \mathbf{b}(k-1) \\ \vdots \\ \mathbf{b}(k-L+1) \end{bmatrix} + \bar{\mathbf{S}}^T \mathbf{n}(k) \\ &= \mathbf{P} \begin{bmatrix} \mathbf{b}(k) \\ \mathbf{b}(k-1) \\ \vdots \\ \mathbf{b}(k-L+1) \end{bmatrix} + \tilde{\mathbf{n}}(k) \end{aligned} \quad (5)$$

where the channel white Gaussian noise vector is

$$\mathbf{n}(k) = [n_1(k) \cdots n_M(k)]^T \quad \text{with} \quad E[\mathbf{n}(k)\mathbf{n}^T(k)] = \sigma_n^2 \mathbf{I} \quad (6)$$

the user signature sequence matrix is

$$\bar{\mathbf{S}} = [\bar{s}_1 \cdots \bar{s}_N] \quad (7)$$

the diagonal user signal amplitude matrix is

$$\mathbf{A} = \text{diag}\{A_1 \cdots A_N\} \quad (8)$$

that is, A_i^2 is the user i signal power; the $M \times LM$ CIR matrix \mathbf{H} has the form

$$\mathbf{H} = \begin{bmatrix} h_0 & h_1 & \cdots & h_{n_h-1} & & \\ & h_0 & h_1 & \cdots & h_{n_h-1} & \\ & & \ddots & \ddots & \cdots & \ddots \\ & & & h_0 & h_1 & \cdots & h_{n_h-1} \end{bmatrix} \quad (9)$$

the $N \times LN$ system matrix \mathbf{P} is defined by

$$\mathbf{P} = \bar{\mathbf{S}}^T \mathbf{H} \begin{bmatrix} \bar{\mathbf{S}}\mathbf{A} & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \bar{\mathbf{S}}\mathbf{A} & \ddots & \vdots \\ \vdots & \ddots & \ddots & \mathbf{0} \\ \mathbf{0} & \cdots & \mathbf{0} & \bar{\mathbf{S}}\mathbf{A} \end{bmatrix} \quad (10)$$

and orthogonal code sequences are assumed, so that the noise vector at the outputs of the chip-matched filters is

$$\tilde{\mathbf{n}}(k) = [\tilde{n}_1(k) \cdots \tilde{n}_N(k)]^T \quad \text{with} \quad E[\tilde{\mathbf{n}}(k)\tilde{\mathbf{n}}^T(k)] = \sigma_n^2 \mathbf{I} \quad (11)$$

The ISI span L depends on the length of the CIR, n_h , related to the length of the chip sequence, M . For $n_h = 1$, $L = 1$; for $1 < n_h \leq M$, $L = 2$; for $M < n_h \leq 2M$, $L = 3$; and so on. The model (5) adopted in this study can readily be extended to the more general case of asynchronous DS-CDMA systems by an appropriate expansion of the system matrix \mathbf{P} [6].

It is worth pointing out that we assume an MUD operating on the outputs $\mathbf{r}(k)$ of a bank of chip-matched filters, as modeled by (5). This model requires the knowledge of all the user codes. The assumption that a receiver knows the user codes is often a reasonable assumption to have. If, however, the user codes are unknown to the receiver, the MUD can directly operate on the chip-rate sampled signals $\mathbf{r}_c(k)$. For the completeness, the model for $\mathbf{r}_c(k)$ is given in Appendix, where it can be seen that operating on $\mathbf{r}_c(k)$ and $\mathbf{r}(k)$ produces equivalent results.

III. THE LINEAR AND OPTIMAL DETECTORS

The linear MUD for user i has the form

$$\hat{b}_i(k) = \text{sgn}(y_L(k)) \quad (12)$$

with

$$y_L(k) = f_L(\mathbf{r}(k)) = \mathbf{w}^T \mathbf{r}(k) \quad (13)$$

where

$$\mathbf{w} = [w_1 \cdots w_N]^T \quad (14)$$

denotes the detector weight vector for user i . The most popular solution for the detector (13) is the MMSE solution given by

$$\mathbf{w}_{\text{MMSE}} = (\sigma_n^2 \mathbf{I} + \mathbf{P}\mathbf{P}^T)^{-1} \mathbf{p}_i \quad (15)$$

where \mathbf{p}_i is the i th column of \mathbf{P} . The linear detector (13) is computationally very simple, and standard least mean square (LMS) or recursive least squares (RLS) algorithms can be used to implement the MMSE solution adaptively.

However, a linear MUD only performs adequately in certain situations. Let the $N_b = 2^{LN}$ possible combinations or sequences of $[\mathbf{b}^T(k) \mathbf{b}^T(k-1) \cdots \mathbf{b}^T(k-L+1)]^T$ be

$$\mathbf{b}^{(j)} = \begin{bmatrix} \mathbf{b}^{(j)}(k) \\ \mathbf{b}^{(j)}(k-1) \\ \vdots \\ \mathbf{b}^{(j)}(k-L+1) \end{bmatrix}, \quad 1 \leq j \leq N_b \quad (16)$$

and $b_i^{(j)}$ the i th element of $\mathbf{b}^{(j)}(k)$. Define the set of the N_b noise-free received signal states as

$$\mathcal{R} = \{\mathbf{r}_j = \mathbf{P}\mathbf{b}^{(j)}, \quad 1 \leq j \leq N_b\}. \quad (17)$$

\mathcal{R} can be partitioned into two subsets

$$\mathcal{R}_{\pm} = \{\mathbf{r}_j \in \mathcal{R} : b_i^{(j)} = \pm 1\}. \quad (18)$$

If \mathcal{R}_- and \mathcal{R}_+ are not linearly separable, a linear MUD will have an irreducible error floor even in the noise-free case, as it can only form a hyperplane in the N -dimensional received signal space.

As the one-shot MUD at a bit period is only concerned with one particular bit from one particular user, the optimal solution can be derived from a one-shot Bayesian classification problem, similar to the channel equalization problem [31]. Thus, the optimal one-shot detector for user i can readily be given as

$$y_B(k) = f_B(\mathbf{r}(k)) = \sum_{\mathbf{r}_j \in \mathcal{R}} \frac{\xi_j b_i^{(j)}}{\sqrt{2\pi}\sigma_n} \exp\left(-\frac{\|\mathbf{r}(k) - \mathbf{r}_j\|^2}{2\sigma_n^2}\right) \quad (19)$$

where ξ_j are *a priori* probabilities of \mathbf{r}_j and $b_i^{(j)} \in \{\pm 1\}$ serve as class labels. Usually, all the \mathbf{r}_j are equiprobable, and $\xi_j = 1/N_b$. The optimal decision is then given by

$$\hat{b}_i(k) = \text{sgn}(y_B(k)). \quad (20)$$

The Bayesian decision variable (19) can also be written as

$$y_B(k) = f_B(\mathbf{r}(k)) = \sum_{j=1}^{N_b} \beta_j b_i^{(j)} \exp\left(-\frac{\|\mathbf{r}(k) - \mathbf{r}_j\|^2}{2\sigma_n^2}\right). \quad (21)$$

An observation of (21) is that it has an equivalent form to an RBF network with Gaussian basis function or kernel.

IV. THE SUPPORT VECTOR MACHINE DETECTOR

The optimal detector (21) requires the knowledge of all the noise-free signal states \mathbf{r}_j , which are unknown to receiver i . In general, the receiver can have access to a block of K training samples $\{\mathbf{r}(k), b_i(k)\}_{k=1}^K$. For notational convenience, let $\mathbf{x}_k = \mathbf{r}(k)$ and $c_k = b_i(k)$, and denote the training set of K noisy received signal vectors as

$$\mathcal{X} = \{\mathbf{x}_j, \quad 1 \leq j \leq K\} \quad (22)$$

and the set of corresponding class labels as

$$\mathcal{C} = \{c_j, \quad 1 \leq j \leq K\}. \quad (23)$$

Applying the standard SVM method [19], an SVM detector can be constructed for user i

$$y_{\text{SVM}}(k) = f_{\text{SVM}}(\mathbf{r}(k)) = \sum_{j=1}^K \bar{g}_j c_j F(\mathbf{r}(k), \mathbf{x}_j) + \bar{\eta} \quad (24)$$

where the set of Lagrangian multipliers $\{\bar{g}_j\}$, denoted in the vector form

$$\bar{\mathbf{g}} = [\bar{g}_1 \cdots \bar{g}_K]^T \quad (25)$$

is the solution of the quadratic programming (QP)

$$\bar{\mathbf{g}} = \arg \min_{\bar{\mathbf{g}}} \left\{ \frac{1}{2} \sum_{j=1}^K \sum_{l=1}^K g_j g_l c_j c_l F(\mathbf{x}_j, \mathbf{x}_l) - \sum_{j=1}^K g_j \right\} \quad (26)$$

with the constraints

$$0 \leq g_j \leq C, \quad 1 \leq j \leq K \quad (27)$$

and

$$\sum_{j=1}^K g_j c_j = 0. \quad (28)$$

In this particular application, it is obviously advantageous to choose the Gaussian kernel function

$$F(\mathbf{x}_j, \mathbf{x}_l) = \exp\left(-\frac{\|\mathbf{x}_j - \mathbf{x}_l\|^2}{2\rho^2}\right) \quad (29)$$

where the width parameter ρ is related to the root mean square σ_n of the channel noise, an estimate of which can be obtained. The offset constant $\bar{\eta}$ is usually determined from the "margin" SVs, i.e., those \mathbf{x}_j s with the corresponding Lagrangian multipliers $0 < \bar{g}_j < C$. Because the optimal decision boundary, defined by $\{\mathbf{r} : f_B(\mathbf{r}) = 0\}$, passes through the origin of the

received signal space and possesses certain symmetric properties due to the symmetric structure of \mathcal{R}_- and \mathcal{R}_+ , $\bar{\eta} = 0$ can be used. With this choice of the offset constant, the equality constraint (28) is no longer needed, and this leads to a simpler optimization task. The user-defined parameter C controls the tradeoff between model complexity and training error. In our application, we will choose C empirically.

The set of SVs, denoted by \mathcal{X}_{SVM} , is given by those \mathbf{x}_j s with nonzero Lagrangian multipliers $0 < \bar{g}_j \leq C$. \mathcal{X}_{SVM} is usually a small subset of the training data set \mathcal{X} . These SVs are determined during the optimization process. Thus the SVM MUD consists of computing the decision variable

$$y_{\text{SVM}}(k) = f_{\text{SVM}}(\mathbf{r}(k)) = \sum_{\mathbf{x}_j \in \mathcal{X}_{\text{SVM}}} \bar{g}_j c_j \exp\left(-\frac{\|\mathbf{r}(k) - \mathbf{x}_j\|^2}{2\rho^2}\right) \quad (30)$$

and making the decision with

$$\hat{b}_i(k) = \text{sgn}(y_{\text{SVM}}(k)). \quad (31)$$

Before presenting some simulation results, we emphasize that the main purpose of this study is to investigate feasibility of the SVM method as a nonlinear MUD, and we use the standard gradient method to solve for the QP problem (26). Such an optimization technique associated with the SVM method requires a considerable amount of computation, especially for a large K . The issue of computational efficiency is more general than the MUD problem. Efficient SVM implementation is an active area of research (see, for example, [23], [37], and [38]).

V. SIMULATION RESULTS

Two simulation examples were used to investigate the proposed SVM MUD and compare its performance with those of the linear MMSE and optimal MUDs. It is worth pointing out again that the linear MMSE MUD and the optimal MUD are designed based on the complete knowledge of the system (the system matrix \mathbf{P} and the noise variance) while the SVM MUD is trained using a block of the noisy received signal samples.

Example 1: This was a two-user system with four chips per bit. The code sequences of the two users were $(+1, +1, -1, -1)$ and $(+1, -1, -1, +1)$, respectively, and the transfer function of the CIR was

$$H(z) = 0.3 + 0.7z^{-1} + 0.3z^{-2}. \quad (32)$$

The two users had equal signal power, that is, the user 1 signal to noise ratio (SNR_1) was equal to that of user 2 (SNR_2). Fig. 2 depicts the two subsets of noise-free signal states for user 1 together with the decision boundaries of the linear MMSE and optimal Bayesian MUDs, given $\text{SNR}_1 = \text{SNR}_2 = 16$ dB. It is clear that for user 1 it is not worth to implement a complex nonlinear detector, as a simple linear detector can perform adequately. However, for user 2, \mathcal{R}_- and \mathcal{R}_+ are not linearly separable and the linear MMSE detector will have an irreducible error floor of 0.125, as illustrated in Fig. 3.

Fig. 2. The set of noise-free signal points and the two decision boundaries (dotted: linear MMSE, solid: optimal) for user 1 of Example 1. $\text{SNR}_1 = \text{SNR}_2 = 16$ dB.

Fig. 3. The set of noise-free signal points and the three decision boundaries (dotted: linear MMSE, thick solid: optimal, thin solid: SVM) for user 2 of Example 1. $\text{SNR}_1 = \text{SNR}_2 = 20$ dB.

| optimal MUD $\log_{10}(\text{BER}) = -1.674$ | | | | |

To construct an SVM MUD for user 2, 160 training data points were generated for each given noise variance. The influence of the parameter C on the model complexity and the bit error rate (BER) of the resulting MUD was first investigated. Tables I and II summarize the results for two different noise conditions, respectively. It can be seen that C has some influence on

Fig. 4. Performance comparison of three MUDs for user 2 of Example 1. $\text{SNR}_1 = \text{SNR}_2$, and the training data set for SVM has 160 samples.

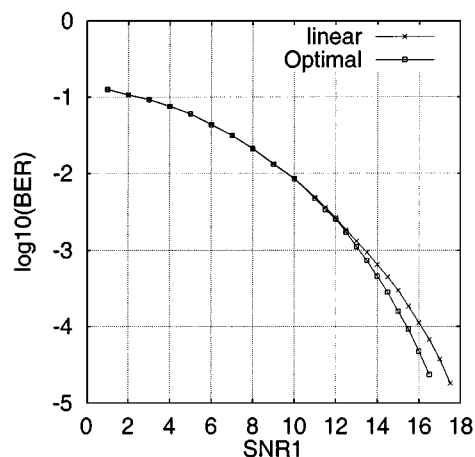

Fig. 5. Performance comparison of two MUDs for user 1 of Example 2. SNR_i , $1 \leq i \leq 3$, are identical.

the construction of SVM model, but the solution is not overly sensitive to it. The decision boundary of the constructed SVM MUD for user 2 is compared with those of the linear MMSE and optimal MUD in Fig. 3, given $\text{SNR}_1 = \text{SNR}_2 = 20$ dB. Fig. 4 plots the BERs of the three MUDs for user 2 under different noise conditions. The results clearly show that the SVM MUD can closely match the performance of the optimal one-shot detector. For the given training set of 160 points, the number of SVs were found typically to be around 40.

Example 2: This was a three-user system with eight chips per bit. The code sequences for the three users were $(+1, +1, +1, +1, -1, -1, -1, -1)$, $(+1, -1, +1, -1, -1, +1, -1, +1)$ and $(+1, -1, -1, +1, -1, +1, +1, -1)$, respectively, and the transfer function of the CIR was

$$H(z) = 0.4 + 0.9z^{-1} + 0.4z^{-2}. \quad (33)$$

The three users had equal signal power. For user 1, the performance of the linear MMSE detector is very close to the optimal detector, as shown in Fig. 5. For users 2 and 3, however, non-linear MUDs are certainly needed, as can be seen in Fig. 6 and Fig. 7.

Fig. 6. Performance comparison of three MUDs for user 2 of Example 2. SNR_i , $1 \leq i \leq 3$, are identical, and the training data set for SVM has 640 samples.

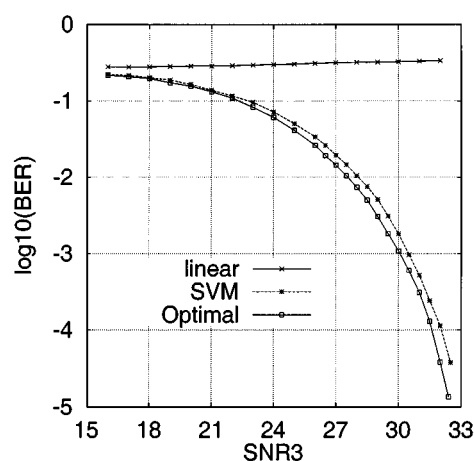

Fig. 7. Performance comparison of three MUDs for user 3 of Example 2. SNR_i , $1 \leq i \leq 3$, are identical, and the training data set for SVM has 640 samples.

TABLE IV
INFLUENCE OF C ON CONSTRUCTING THE SVM MUD FOR USER 2 OF EXAMPLE 2. $\text{SNR}_i = 25$ dB FOR $1 \leq i \leq 3$, AND THE NUMBER OF TRAINING DATA IS 640

| C | 0.6 | 0.8 | 1.0 | 5.0 |
|--|--------|--------|--------|--------|
| number of SVs | 261 | 240 | 229 | 181 |
| $\log_{10}(\text{BER})$ | -1.442 | -1.454 | -1.459 | -1.429 |
| optimal MUD $\log_{10}(\text{BER}) = -1.521$ | | | | |

The number of training data for constructing SVM models was 640 for each given noise condition. The influence of C on the model complexity and performance was again found to be not overly sensitive, as illustrated in Tables III and IV for the case of user 2 with two different noise conditions. From the

training data set of 640 points, typically around 200 SVs were selected. The BERs of the resulting SVM MUDs for users 2 and 3 are given in Figs. 6 and 7, respectively, in comparison with the corresponding linear MMSE and optimal one-shot MUDs. The results again demonstrate that the SVM MUD can closely approximate the performance of the optimal detector.

We would like to point out that, even though orthogonal spreading sequences were used in the simulation, the orthogonality was destroyed by the ISI channel. Interfering signals in the simulation were also kept to be relatively strong. The desired user signal to interference ratio was 0 dB for Example 1 and approximately -5 dB for Example 2.

VI. COMPARISON WITH THE CLUSTERING RBF DETECTOR

Because of its intimate link with the optimal one-shot detector (21), the RBF model of the form

$$y_{\text{RBF}}(k) = f_{\text{RBF}}(\mathbf{r}(k)) = \sum_{j=1}^{N_c} \alpha_j \exp\left(-\frac{\|\mathbf{r}(k) - \mathbf{c}_j\|^2}{2\rho^2}\right) \quad (34)$$

is a good candidate for nonlinear MUD. Assuming the number of the users is known, the number of the centers should be $N_c = N_b$, and the optimal RBF centers are the set of noise-free signal states \mathcal{R} . The width ρ is an estimate of the noise standard deviation, and the weights α_j can simply be set according to the class label of the corresponding center, or trained using the LMS or RLS algorithm. Such an RBF MUD achieves the exact optimal MUD.

The most efficient way of adaptively placing the RBF centers to the desired noise-free signal states is the supervised cluster algorithm [31]. In the multiuser detection context, the algorithm will require to know all the users' bits from $k - L + 1$ to k , and this is impractical for downlink. Thus, unsupervised clustering has to be used. The enhanced κ -means clustering algorithm [32]–[34] is ideal for the RBF MUD. By using a cluster variation-weighted measure, this algorithm always converges to an optimal or near optimal cluster configuration, independent of the initial center locations. Furthermore, the variance of every cluster is equal after convergence. This property is particular relevant to our application since all the cluster variances in this case should be equal.

The enhanced κ -means clustering method [33] adjusts the RBF centers according to

$$\mathbf{c}_j(k+1) = \mathbf{c}_j(k) + \mathcal{M}_j(\mathbf{r}(k))\mu(\mathbf{r}(k) - \mathbf{c}_j(k)) \quad (35)$$

where the membership function

$$\mathcal{M}_j(\mathbf{r}) = \begin{cases} 1, & \text{if } v_j \|\mathbf{r} - \mathbf{c}_j\|^2 \leq v_l \|\mathbf{r} - \mathbf{c}_l\|^2 \forall l \neq j \\ 0, & \text{otherwise} \end{cases} \quad (36)$$

and v_j is the ‘‘variance’’ of the j th cluster. To estimate v_j , the following rule is used:

$$v_j(k+1) = \gamma v_j(k) + (1 - \gamma) \mathcal{M}_j(\mathbf{r}(k)) \|\mathbf{r}(k) - \mathbf{c}_j(k)\|^2 \quad (37)$$

where γ is a constant slightly less than 1.0. The initial $v_j(0)$, $1 \leq j \leq N_c$, can be set to the same small value. The learning rate

for centers, μ , is self-adjusting based on an ‘‘entropy’’ formula [33].

To illustrate the optimal properties of the enhanced κ -means clustering method, consider the user 2 of Example 1 given in the previous section with $\text{SNR}_1 = \text{SNR}_2 = 20$ dB. Started from $\mathbf{c}_j(0) = \mathbf{0}$, $1 \leq j \leq 16$, the trajectories of cluster centers in 10 000-samples adaptation are shown in Fig. 8. Table V summarizes the final cluster center positions and variations, in comparison with the true noise-free signal states. Similar clustering performance can be obtained with only 4000 data samples when the first 16 data points are used as the initial centers, as illustrated in Fig. 9. The BER performance of such a clustering RBF MUD is indistinguishable with the optimal one-shot MUD.

The following comparisons for the SVM and clustering RBF MUDs can be made. The adaptation of the SVM model is based on a block of data while the clustering RBF is implemented sample-by-sample. The sample-by-sample adjustment is more desired in real-time applications. The clustering RBF MUD can achieve the optimal MUD, provided that a sufficient number of training data are available. The SVM MUD has an important advantage as it requires a relatively short training data set. For our simple Example 1, The SVM MUD requires less than 200 training data. In contrast, the clustering RBF MUD needs a few thousands of training data, due to the nature of the unsupervised clustering process. Such a long training data length is difficult to achieve in practice. As the SVM approach places the kernel centers directly on some noisy data points called SVs, it will require more centers than the clustering RBF model. For Example 1, the SVM MUD needs typically 40 kernels to closely match the optimal performance, while the clustering RBF MUD has only 16 kernel functions.

VII. CONCLUSION

The SVM technique has been applied to adaptive nonlinear multiuser detection for DS-CDMA systems. It has been shown that the SVM MUD can closely match the performance of the optimal Bayesian one-shot detector with an important advantage of requiring a relatively small training data set. Comparisons with an adaptive clustering RBF MUD have been made. A disadvantage of the SVM approach is its block-based adaptation nature. Although the SVM approach has an excellent model reduction ability, the resulting SVM MUD still has a larger model size, in comparison with the number of noise-free signal states. Future research will investigate how to reduce the number of support vectors further without sacrificing the BER performance too much and how to incorporate the sample-by-sample adaptive methodology with the SVM approach.

Fig. 8. Cluster center trajectories using the enhanced κ -means clustering for user 2 of Example 1. $\text{SNR}_1 = \text{SNR}_2 = 20$ dB, initial centers are all placed at the origin, and 10 000 data samples are used.

Fig. 9. Cluster center trajectories using the enhanced κ -means clustering for user 2 of Example 1. $\text{SNR}_1 = \text{SNR}_2 = 20$ dB, the first 16 data points are used as initial centers, and 4 000 data samples are used.

APPENDIX

During one bit period, the chip rate sampler produces M samples

$$\mathbf{r}_c(k) = [r_{c,1}(k) \cdots r_{c,M}(k)]^T. \quad (38)$$

The baseband model for $\mathbf{r}_c(k)$ is represented by [36]

$$\mathbf{r}_c(k) = \mathbf{H} \begin{bmatrix} \bar{\mathbf{S}}\mathbf{A} & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \bar{\mathbf{S}}\mathbf{A} & \ddots & \vdots \\ \vdots & \ddots & \ddots & \mathbf{0} \\ \mathbf{0} & \cdots & \mathbf{0} & \bar{\mathbf{S}}\mathbf{A} \end{bmatrix} \begin{bmatrix} \mathbf{b}(k) \\ \mathbf{b}(k-1) \\ \vdots \\ \mathbf{b}(k-L+1) \end{bmatrix} + \mathbf{n}(k) \quad (39)$$

$$= \mathbf{P}_c \begin{bmatrix} \mathbf{b}(k) \\ \mathbf{b}(k-1) \\ \vdots \\ \mathbf{b}(k-L+1) \end{bmatrix} + \mathbf{n}(k)$$

where the $M \times LN$ system matrix \mathbf{P}_c is defined as

$$\mathbf{P}_c = \mathbf{H} \begin{bmatrix} \bar{\mathbf{S}}\mathbf{A} & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \bar{\mathbf{S}}\mathbf{A} & \ddots & \vdots \\ \vdots & \ddots & \ddots & \mathbf{0} \\ \mathbf{0} & \cdots & \mathbf{0} & \bar{\mathbf{S}}\mathbf{A} \end{bmatrix}. \quad (40)$$

An MUD can directly operate on $\mathbf{r}_c(k)$, instead of the chip-matched filtered version $\mathbf{r}(k)$. For example, an alternative linear MUD takes the form

$$y_L(k) = \mathbf{w}_c^T \mathbf{r}_c(k) \quad (41)$$

with the M -dimensional weight vector $\mathbf{w}_c = [w_{c,1} \cdots w_{c,M}]^T$. It is well-known that this linear MUD is equivalent to the linear MUD of (13). In the M -dimensional space $\mathbf{r}_c(k)$, the set of the N_b noise-free received signal states is defined by

$$\mathcal{R}_c = \{\mathbf{r}_{c,j} = \mathbf{P}_c \mathbf{b}^{(j)}, \quad 1 \leq j \leq N_b\}. \quad (42)$$

An optimal Bayesian one-shot detector, similar to (21), can alternatively be defined.
